# 1 Pipelining

## 1.1 Introduction of Pipelining

*Pipelining* is an implementation technique whereby multiple instructions are overlapped in execution; it takes advantage of parallelism that exists among the actions needed to execute an instruction.<sup>[1]</sup>

### 1.1.1 Laundry Example

Suppose we have many loads of clothes to wash, dry and fold.

- Each step (washing, drying and folding) is called a *pipe stage* or a *pipe segment*.
- *Latency* is the total time spent on a single task, which is not improved by pipelining. Unbalanced lengths of pipe stages reduces speedup.
- *Throughput* is defined as the number of loads of clothes per minute. It shows how often a load of clothes exits the pipeline.
- The time required between moving an instruction one step down the pipeline is a *processor cycle*. In a computer, this processor cycle is usually 1 clock cycle.<sup>[1]</sup>

### 1.1.2 Speedup from Pipelining

Throughput is what matters.

- Unbalanced lengths of pipe stages reduces speedup.
- Handover time between pipe stages reduces speedup.

To improve the efficiency of a pipeline, one should balance the length of each pipeline stage. If the stages are perfectly balanced, then the time per instruction on the pipeline processor is equal to (under ideal conditions)

$$\frac{\text{Time per instruction on unpipelined machine}}{\text{Number of pipe stages}}$$

and the throughput of the pipeline is equal to

$$\text{Number of pipe stages} \times \text{Throughput on unpipelined machine}$$

## 1.2 The Basics of a RISC Instruction Set

### 1.2.1 Introduction of RISC

A RISC<sup>1</sup> is a computer whose instruction set architecture that has lower *cycles per instruction* (CPI) than a CISC<sup>2</sup>.

MIPS is a RISC instruction set architecture.

<sup>2</sup>complex instruction set computer

## Key Properties of RISC Architectures<sup>[1]</sup>

- All operations on data apply to data in registers and typically change the entire register (32 or 64 bits per register).
- Only load and store operations can affect memory. Load and store operations that load or store less than a full register are often available.
- The instruction formats are few in number, with all instructions typically being one size.

These properties make the implementation of pipelining simple.

Most RISC architectures like MIPS have three classes of instructions:

1. ALU<sup>3</sup> instructions
2. Load and store instructions
3. Branches and jumps

### 1.2.2 Implementation of a RISC Instruction Set

The implementation here will focus only on a pipeline for an integer subset of a RISC architecture that consists of load-store word, branch, and integer ALU operations.

**Implementation Without Pipelining<sup>[1]</sup>** Every instruction in the RISC subset can be implemented in at most 5 clock cycles as follows:

1. *Instruction fetch cycle* (IF):

Send the program counter (PC) to memory and fetch the current instruction from memory. Update the PC to the next sequential PC by adding 4 (since each instruction is 4 bytes) to the PC.

2. *Instruction decode / register fetch cycle* (ID):

Decode the instruction and read the registers corresponding to register source specifiers from the register file. Do the equality test on the registers as they are read, for a possible branch. Sign-extend (introduced later) the offset field of the instruction in case it is needed. Compute the possible branch target address by adding the sign-extended offset to the incremented PC.

Decoding is done in parallel with reading registers, which is possible because the register specifiers are at a fixed location in a RISC instruction. This technique is known as *fixed-field decoding*. It may read a register that we don't use, and it doesn't help but also doesn't hurt performance.

3. *Execution / effective address cycle* (EX):

The ALU operates on the operands prepared in the prior cycle, performing one of three functions depending on the instruction type.

- Memory reference — The ALU adds the base register and the offset to form the effective address.

---

<sup>3</sup>Arithmetic logic unit

- Register-Register ALU instruction — The ALU performs the operation specified by the ALU opcode on the values read from the register file.
- Register-Immediate ALU instruction — The ALU performs the operation specified by the ALU opcode on the first value read from the register file and the sign-extended immediate.

In a load-store architecture the effective address and execution cycles can be combined into a single clock cycle, since no instruction needs to do both of them.

**Sign Extension** In computer arithmetic, sign extension is the operation of increasing the number of bits of a binary number while preserving the number's sign and value. This is done by appending digits (same as the sign bit) to the most significant side of the number, following a procedure dependent on the particular signed number representation used.

For example:

- “00 1010” (decimal positive 10) → “0000 0000 0000 1010”
- “11 1111 0001” (decimal negative 15) → “1111 1111 1111 0001”
